Street lighting is very important for road safety and for people moving around at night. In many cities, traditional street lights are left on throughout the night even when there is little or no activity on the road. This leads to unnecessary energy consumption and increases electricity costs. Because of this problem, engineers have begun to develop automatic lighting systems that can control when lights turn on and off.

In this project, an automatic street light system was designed using an Arduino Uno microcontroller. The system uses a Light Dependent Resistor (LDR) to measure the level of light in the environment. When the surrounding environment becomes dark, the

Arduino detects the change in voltage from the LDR and prepares the lighting system for operation.

A Passive Infrared (PIR) sensor is also included in the design to detect movement from pedestrians or vehicles. When motion is detected during nighttime, the LED street light turns on automatically. If no motion is detected, the system keeps the lights off, helping to conserve electrical energy.

The system was first tested using simulation tools such as Proteus and Tinkercad before building the real hardware prototype. Simulation helps engineers verify that the circuit and program logic work correctly before

constructing the physical system. After successful simulation, the components were assembled and tested under different lighting conditions to ensure the system operates as expected.

Abstract

Street lighting is very important for road safety and for people moving around at night. In many cities, traditional street lights are left on throughout the night even when there is little or no activity on the road. This leads to unnecessary energy consumption and increases electricity costs. Because of this problem, engineers have begun to develop automatic lighting systems that can control when lights turn on and off.

In this project, an automatic street light system was designed using an Arduino Uno microcontroller. The system uses a Light Dependent Resistor (LDR) to measure the level of light in the environment. When the surrounding environment becomes dark, the Arduino detects the change in voltage from the LDR and prepares the lighting system for operation.

A Passive Infrared (PIR) sensor is also included in the design to detect movement from pedestrians or vehicles. When motion is detected during nighttime, the LED street light turns on automatically. If no motion is detected, the system keeps the lights off, helping to conserve electrical energy.

The system was first tested using simulation tools such as Proteus and Tinkercad before building the real hardware prototype. Simulation helps engineers verify that the circuit and program logic work correctly before constructing the physical system. After successful simulation, the components were assembled and tested under different lighting conditions to ensure the system operates as expected.

In this project, an automatic street light system was designed using an Arduino Uno microcontroller. The system uses a Light Dependent Resistor (LDR) to measure the level of light in the environment. When the surrounding environment becomes dark, the Arduino detects the change in voltage from the LDR and prepares the lighting system for operation.

A Passive Infrared (PIR) sensor is also included in the design to detect movement from pedestrians or vehicles. When motion is detected during nighttime, the LED street light turns on automatically. If no motion is detected, the system keeps the lights off, helping to conserve electrical energy.

The system was first tested using simulation tools such as Proteus and Tinkercad before building the real hardware prototype. Simulation helps engineers verify that the circuit and program logic work correctly before constructing the physical system. After successful

simulation, the components were assembled and tested under different lighting conditions to ensure the system operates as expected.

Street lighting is very important for road safety and for people moving around at night. In many cities, traditional street lights are left on throughout the night even when there is little or no activity on the road. This leads to unnecessary energy consumption and increases electricity costs. Because of this problem, engineers have begun to develop automatic lighting systems that can control when lights turn on and off.

When the surrounding environment becomes dark, the Arduino detects the change in voltage from the LDR and prepares the lighting system for operation.

A Passive Infrared (PIR) sensor is also included in the design to detect movement from pedestrians or vehicles. When motion is detected during nighttime, the LED street light turns on automatically. If no motion is detected, the system keeps the lights off, helping to conserve electrical energy.

The system was first tested using simulation tools such as Proteus and Tinkercad before building the real hardware prototype. Simulation helps engineers verify that the circuit and program logic work correctly before constructing the physical system. After successful simulation, the components were assembled and tested under different lighting conditions to ensure the system operates as expected.

Street lighting is very important for road safety and for people moving around at night. In many cities, traditional street lights are left on throughout the night even when there is little or no activity on the road. This leads to unnecessary energy consumption and increases electricity costs. Because of this problem, engineers have begun to develop automatic lighting systems that can control when lights turn on and off.

In this project, an automatic street light system was designed using an Arduino Uno microcontroller. The system uses a Light Dependent Resistor (LDR) to measure the level of light in the environment. When the surrounding environment becomes dark, the Arduino detects the change in voltage from the LDR and prepares the lighting system for operation.

A Passive Infrared (PIR) sensor is also included in the design to detect movement from pedestrians or vehicles. When motion is detected during nighttime, the LED street light turns on automatically. If no motion is detected, the system keeps the lights off, helping to conserve electrical energy.

The system was first tested using simulation tools such as Proteus and Tinkercad before building the real hardware prototype. Simulation helps engineers verify that the circuit and program logic work correctly before constructing the physical system. After successful

simulation, the components were assembled and tested under different lighting conditions to ensure the system operates as expected.

The system was first tested using simulation tools such as Proteus and Tinkercad before building the real hardware prototype. Simulation helps engineers verify that the circuit and program logic work correctly before constructing the physical system. After successful

simulation, the components were assembled and tested under different lighting conditions to ensure the system operates as expected.

Street lighting is very important for road safety and for people moving around at night. In many cities, traditional street lights are left on throughout the night even when there is little or no activity on the road. This leads to unnecessary energy consumption and increases electricity costs. Because of this problem, engineers have begun to develop automatic lighting systems that can control when lights turn on and off.

In this project, an automatic street light system was designed using an Arduino Uno microcontroller. The system uses a Light Dependent Resistor (LDR) to measure the level of light in the environment. When the surrounding environment becomes dark, the Arduino detects the change in voltage from the LDR and prepares the lighting system for operation.

A Passive Infrared (PIR) sensor is also included in the design to detect movement from pedestrians or vehicles. When motion is detected during nighttime, the LED street light turns on automatically. If no motion is detected, the system keeps the lights off, helping to conserve electrical energy.

The system was first tested using simulation tools such as Proteus and Tinkercad before building the real hardware prototype. Simulation helps engineers verify that the circuit and program logic work correctly before constructing the physical system. After successful simulation, the components were assembled and tested under different lighting conditions to ensure the system operates as expected.

This leads to unnecessary energy consumption and increases electricity costs. Because of this problem, engineers have begun to develop automatic lighting systems that can control when lights turn on and off.

In this project, an automatic street light system was designed using an Arduino Uno microcontroller. The system uses a Light Dependent Resistor (LDR) to measure the level of light in the environment. When the surrounding environment becomes dark, the Arduino detects the change in voltage from the LDR and prepares the lighting system for operation.

A Passive Infrared (PIR) sensor is also included in the design to detect movement from pedestrians or vehicles. When motion is detected during nighttime, the LED street light turns on automatically. If no motion is detected, the system keeps the lights off, helping to conserve electrical energy.

The system was first tested using simulation tools such as Proteus and Tinkercad before building the real hardware prototype. Simulation helps engineers verify that the circuit and program logic work correctly before constructing the physical system. After successful

simulation, the components were assembled and tested under different lighting conditions to ensure the system operates as expected.

Street lighting is very important for road safety and for people moving around at night. In many cities, traditional street lights are left on throughout the night even when there is little or no activity on the road. This leads to unnecessary energy consumption and increases electricity costs. Because of this problem, engineers have begun to develop automatic lighting systems that can control when lights turn on and off.

5.4 Energy Consumption Analysis

Street lighting is very important for road safety and for people moving around at night. In many cities, traditional street lights are left on throughout the night even when there is little or no activity on the road. This leads to unnecessary energy consumption and increases electricity costs. Because of this problem, engineers have begun to develop automatic lighting systems that can control when lights turn on and off.

In this project, an automatic street light system was designed using an Arduino Uno microcontroller. The system uses a Light Dependent Resistor (LDR) to measure the level of light in the environment. When the surrounding environment becomes dark, the Arduino detects the change in voltage from the LDR and prepares the lighting system for operation.

A Passive Infrared (PIR) sensor is also included in the design to detect movement from pedestrians or vehicles. When motion is detected during nighttime, the LED street light turns on automatically. If no motion is detected, the system keeps the lights off, helping to conserve electrical energy.

The system was first tested using simulation tools such as Proteus and Tinkercad before building the real hardware prototype. Simulation helps engineers verify that the circuit and program logic work correctly before constructing the physical system. After successful simulation, the components were assembled and tested under different lighting conditions to ensure the system operates as expected.

Street lighting is very important for road safety and for people moving around at night. In many cities, traditional street lights are left on throughout the night even when there is little or no activity on the road. This leads to unnecessary energy consumption and increases electricity costs. Because of this problem, engineers have begun to develop automatic lighting systems that can control when lights turn on and off.

A Passive Infrared (PIR) sensor is also included in the design to detect movement from pedestrians or vehicles. When motion is detected during nighttime, the LED street light turns on automatically. If no motion is detected, the system keeps the lights off, helping to conserve electrical energy.

The system was first tested using simulation tools such as Proteus and Tinkercad before building the real hardware prototype. Simulation helps engineers verify that the circuit and program logic work correctly before constructing the physical system. After successful simulation, the components were assembled and tested under different lighting conditions to ensure the system operates as expected.

References

Street lighting is very important for road safety and for people moving around at night. In many cities, traditional street lights are left on throughout the night even when there is little or no activity on the road. This leads to unnecessary energy consumption and increases electricity costs. Because of this problem, engineers have begun to develop automatic lighting systems that can control when lights turn on and off.

In this project, an automatic street light system was designed using an Arduino Uno microcontroller. The system uses a Light Dependent Resistor (LDR) to measure the level of light in the environment. When the surrounding environment becomes dark, the Arduino detects the change in voltage from the LDR and prepares the lighting system for operation.

Street lighting is very important for road safety and for people moving around at night. In many cities, traditional street lights are left on throughout the night even when there is little or no activity on the road. This leads to unnecessary energy consumption and increases electricity costs. Because of this problem, engineers have begun to develop automatic lighting systems that can control when lights turn on and off.

In this project, an automatic street light system was designed using an Arduino Uno microcontroller. The system uses a Light Dependent Resistor (LDR) to measure the level of light in the environment. When the surrounding environment becomes dark, the Arduino detects the change in voltage from the LDR and prepares the lighting system for operation.

A Passive Infrared (PIR) sensor is also included in the design to detect movement from pedestrians or vehicles. When motion is detected during nighttime, the LED street light turns on automatically. If no motion is detected, the system keeps the lights off, helping to conserve electrical energy.

The system was first tested using simulation tools such as Proteus and Tinkercad before building the real hardware prototype. Simulation helps engineers verify that the circuit and program logic work correctly before constructing the physical system. After successful simulation, the components were assembled and tested under different lighting conditions to ensure the system operates as expected.

1.2 Problem Statement

Street lighting is very important for road safety and for people moving around at night. In many cities, traditional street lights are left on throughout the night even when there is little or no activity on the road. This leads to unnecessary energy consumption and increases electricity costs. Because of this problem, engineers have begun to develop automatic lighting systems that can control when lights turn on and off.

In this project, an automatic street light system was designed using an Arduino Uno microcontroller. The system uses a Light Dependent Resistor (LDR) to measure the level of light in the environment. When the surrounding environment becomes dark, the Arduino detects the change in voltage from the LDR and prepares the lighting system for operation.

In this project, an automatic street light system was designed using an Arduino Uno microcontroller. The system uses a Light Dependent Resistor (LDR) to measure the level of light in the environment. When the surrounding environment becomes dark, the Arduino detects the change in voltage from the LDR and prepares the lighting system for operation.

A Passive Infrared (PIR) sensor is also included in the design to detect movement from pedestrians or vehicles. When motion is detected during nighttime, the LED street light turns on automatically. If no motion is detected, the system keeps the lights off, helping to conserve electrical energy.

The system was first tested using simulation tools such as Proteus and Tinkercad before building the real hardware prototype. Simulation helps engineers verify that the circuit and program logic work correctly before constructing the physical system. After successful

simulation, the components were assembled and tested under different lighting conditions to ensure the system operates as expected.

Street lighting is very important for road safety and for people moving around at night. In many cities, traditional street lights are left on throughout the night even when there is little or no activity on the road. This leads to unnecessary energy consumption and increases electricity costs. Because of this problem, engineers have begun to develop automatic lighting systems that can control when lights turn on and off.

In this project, an automatic street light system was designed using an Arduino Uno microcontroller. The system uses a Light Dependent Resistor (LDR) to measure the level of light in the environment. When the surrounding environment becomes dark, the Arduino detects the change in voltage from the LDR and prepares the lighting system for operation.

When the surrounding environment becomes dark, the Arduino detects the change in voltage from the LDR and prepares the lighting system for operation.

A Passive Infrared (PIR) sensor is also included in the design to detect movement from pedestrians or vehicles. When motion is detected during nighttime, the LED street light turns on automatically. If no motion is detected, the system keeps the lights off, helping to conserve electrical energy.

The system was first tested using simulation tools such as Proteus and Tinkercad before building the real hardware prototype. Simulation helps engineers verify that the circuit and program logic work correctly before constructing the physical system. After successful simulation, the components were assembled and tested under different lighting conditions to ensure the system operates as expected.

Street lighting is very important for road safety and for people moving around at night. In many cities, traditional street lights are left on throughout the night even when there is little or no activity on the road. This leads to unnecessary energy consumption and increases electricity costs. Because of this problem, engineers have begun to develop automatic lighting systems that can control when lights turn on and off.

In this project, an automatic street light system was designed using an Arduino Uno microcontroller. The system uses a Light Dependent Resistor (LDR) to measure the level of light in the environment. When the surrounding environment becomes dark, the Arduino detects the change in voltage from the LDR and prepares the lighting system for operation.

A Passive Infrared (PIR) sensor is also included in the design to detect movement from pedestrians or vehicles. When motion is detected during nighttime, the LED street light turns on automatically. If no motion is detected, the system keeps the lights off, helping to conserve electrical energy.

The system was first tested using simulation tools such as Proteus and Tinkercad before building the real hardware prototype. Simulation helps engineers verify that the circuit and program logic work correctly before constructing the physical system. After successful

simulation, the components were assembled and tested under different lighting conditions to ensure the system operates as expected.

Street lighting is very important for road safety and for people moving around at night. In many cities, traditional street lights are left on throughout the night even when there is little or no activity on the road. This leads to unnecessary energy consumption and increases electricity costs. Because of this problem, engineers have begun to develop automatic lighting systems that can control when lights turn on and off.

In this project, an automatic street light system was designed using an Arduino Uno microcontroller. The system uses a Light Dependent Resistor (LDR) to measure the level of light in the environment. When the surrounding environment becomes dark, the Arduino detects the change in voltage from the LDR and prepares the lighting system for operation.

A Passive Infrared (PIR) sensor is also included in the design to detect movement from pedestrians or vehicles. When motion is detected during nighttime, the LED street light turns on automatically. If no motion is detected, the system keeps the lights off, helping to conserve electrical energy.

The system was first tested using simulation tools such as Proteus and Tinkercad before building the real hardware prototype. This leads to unnecessary energy consumption and increases electricity costs. Because of this problem, engineers have begun to develop automatic lighting systems that can control when lights turn on and off.

In this project, an automatic street light system was designed using an Arduino Uno microcontroller. The system uses a Light Dependent Resistor (LDR) to measure the level of light in the environment. When the surrounding environment becomes dark, the Arduino detects the change in voltage from the LDR and prepares the lighting system for operation.

A Passive Infrared (PIR) sensor is also included in the design to detect movement from pedestrians or vehicles. When motion is detected during nighttime, the LED street light turns on automatically. If no motion is detected, the system keeps the lights off, helping to conserve electrical energy.

The system was first tested using simulation tools such as Proteus and Tinkercad before building the real hardware prototype. Simulation helps engineers verify that the circuit and program logic work correctly before constructing the physical system. After successful

simulation, the components were assembled and tested under different lighting conditions to ensure the system operates as expected.

Street lighting is very important for road safety and for people moving around at night. In many cities, traditional street lights are left on throughout the night even when there is little or no activity on the road. This leads to unnecessary energy consumption and increases electricity costs. Because of this problem, engineers have begun to develop automatic lighting systems that can control when lights turn on and off.

In this project, an automatic street light system was designed using an Arduino Uno microcontroller. The system uses a Light Dependent Resistor (LDR) to measure the level of light in the environment. In this project, an automatic street light system was designed using an Arduino Uno microcontroller. The system uses a Light Dependent Resistor (LDR) to measure the level of light in the environment. When the surrounding environment becomes dark, the Arduino detects the change in voltage from the LDR and prepares the lighting system for operation.

A Passive Infrared (PIR) sensor is also included in the design to detect movement from pedestrians or vehicles. When motion is detected during nighttime, the LED street light turns on automatically. If no motion is detected, the system keeps the lights off, helping to conserve electrical energy.

The system was first tested using simulation tools such as Proteus and Tinkercad before building the real hardware prototype. Simulation helps engineers verify that the circuit and program logic work correctly before constructing the physical system. After successful simulation, the components were assembled and tested under different lighting conditions to ensure the system operates as expected.

Street lighting is very important for road safety and for people moving around at night. In many cities, traditional street lights are left on throughout the night even when there is little or no activity on the road. This leads to unnecessary energy consumption and increases electricity costs. Because of this problem, engineers have begun to develop automatic lighting systems that can control when lights turn on and off.

After successful simulation, the components were assembled and tested under different lighting conditions to ensure the system operates as expected.

Abstract

Street lighting is very important for road safety and for people moving around at night. In many cities, traditional street lights are left on throughout the night even when there is little or no activity on the road. This leads to unnecessary energy consumption and increases electricity costs. Because of this problem, engineers have begun to develop automatic lighting systems that can control when lights turn on and off.

In this project, an automatic street light system was designed using an Arduino Uno microcontroller. The system uses a Light Dependent Resistor (LDR) to measure the level of light in the environment. When the surrounding environment becomes dark, the Arduino detects the change in voltage from the LDR and prepares the lighting system for operation.

A Passive Infrared (PIR) sensor is also included in the design to detect movement from pedestrians or vehicles. When motion is detected during nighttime, the LED street light turns on automatically. If no motion is detected, the system keeps the lights off, helping to conserve electrical energy.

The system was first tested using simulation tools such as Proteus and Tinkercad before building the real hardware prototype. Simulation helps engineers verify that the circuit and program logic work correctly before constructing the physical system. After successful simulation, the components were assembled and tested under different lighting conditions to ensure the system operates as expected.

This leads to unnecessary energy consumption and increases electricity costs. Because of this problem, engineers have begun to develop automatic lighting systems that can control when lights turn on and off.

In this project, an automatic street light system was designed using an Arduino Uno microcontroller. The system uses a Light Dependent Resistor (LDR) to measure the level of light in the environment. When the surrounding environment becomes dark, the Arduino detects the change in voltage from the LDR and prepares the lighting system for operation.

A Passive Infrared (PIR) sensor is also included in the design to detect movement from pedestrians or vehicles. When motion is detected during nighttime, the LED street light turns on automatically. If no motion is detected, the system keeps the lights off, helping to conserve electrical energy.

The system was first tested using simulation tools such as Proteus and Tinkercad before building the real hardware prototype. Simulation helps engineers verify that the circuit and program logic work correctly before constructing the physical system. After successful simulation, the components were assembled and tested under different lighting conditions to ensure the system operates as expected.

1.5 Scope and Limitations

Street lighting is very important for road safety and for people moving around at night. In many cities, traditional street lights are left on throughout the night even when there is little or no activity on the road. This leads to unnecessary energy consumption and increases electricity costs. Because of this problem, engineers have begun to develop automatic lighting systems that can control when lights turn on and off.

In this project, an automatic street light system was designed using an Arduino Uno microcontroller. The system uses a Light Dependent Resistor (LDR) to measure the level of light in the environment. In this project, an automatic street light system was designed using an Arduino Uno microcontroller. The system uses a Light Dependent Resistor (LDR) to measure the level of light in the environment. When the surrounding environment becomes dark, the Arduino detects the change in voltage from the LDR and prepares the lighting system for operation.

A Passive Infrared (PIR) sensor is also included in the design to detect movement from pedestrians or vehicles. When motion is detected during nighttime, the LED street light turns on automatically. If no motion is detected, the system keeps the lights off, helping to conserve electrical energy.

The system was first tested using simulation tools such as Proteus and Tinkercad before building the real hardware prototype. Simulation helps engineers verify that the circuit and program logic work correctly before constructing the physical system. After successful

simulation, the components were assembled and tested under different lighting conditions to ensure the system operates as expected.

Street lighting is very important for road safety and for people moving around at night. In many cities, traditional street lights are left on throughout the night even when there is little or no activity on the road. This leads to unnecessary energy consumption and increases electricity costs. Because of this problem, engineers have begun to develop automatic lighting systems that can control when lights turn on and off.

A Passive Infrared (PIR) sensor is also included in the design to detect movement from pedestrians or vehicles. When motion is detected during nighttime, the LED street light turns on automatically. If no motion is detected, the system keeps the lights off, helping to conserve electrical energy.

The system was first tested using simulation tools such as Proteus and Tinkercad before building the real hardware prototype. Simulation helps engineers verify that the circuit and program logic work correctly before constructing the physical system. After successful simulation, the components were assembled and tested under different lighting conditions to ensure the system operates as expected.

Street lighting is very important for road safety and for people moving around at night. In many cities, traditional street lights are left on throughout the night even when there is little or no activity on the road. This leads to unnecessary energy consumption and increases electricity costs. Because of this problem, engineers have begun to develop automatic lighting systems that can control when lights turn on and off.

In this project, an automatic street light system was designed using an Arduino Uno microcontroller. The system uses a Light Dependent Resistor (LDR) to measure the level of light in the environment. When the surrounding environment becomes dark, the Arduino detects the change in voltage from the LDR and prepares the lighting system for operation.

A Passive Infrared (PIR) sensor is also included in the design to detect movement from pedestrians or vehicles. When motion is detected during nighttime, the LED street light turns on automatically. If no motion is detected, the system keeps the lights off, helping to conserve electrical energy.

simulation, the components were assembled and tested under different lighting conditions to ensure the system operates as expected.

Street lighting is very important for road safety and for people moving around at night. In many cities, traditional street lights are left on throughout the night even when there is little or no activity on the road. This leads to unnecessary energy consumption and increases electricity costs. Because of this problem, engineers have begun to develop automatic lighting systems that can control when lights turn on and off.

In this project, an automatic street light system was designed using an Arduino Uno microcontroller. The system uses a Light Dependent Resistor (LDR) to measure the level of light in the environment. When the surrounding environment becomes dark, the Arduino detects the change in voltage from the LDR and prepares the lighting system for operation.

A Passive Infrared (PIR) sensor is also included in the design to detect movement from pedestrians or vehicles. When motion is detected during nighttime, the LED street light turns on automatically. If no motion is detected, the system keeps the lights off, helping to conserve electrical energy.

The system was first tested using simulation tools such as Proteus and Tinkercad before building the real hardware prototype. Simulation helps engineers verify that the circuit and program logic work correctly before constructing the physical system. After successful simulation, the components were assembled and tested under different lighting conditions to ensure the system operates as expected.
